

$$\mu_y = f(\eta_1, \dots, \eta_n) + \frac{1}{2} \sum_{i=1}^n \frac{\partial^2 f(x_1, \dots, x_n)}{\partial (x_i)^2} \Big|_{x_i} \sigma_i^2$$

$$\sigma_y^2 = \sum_{i=1}^n \left(\frac{\partial f(x_1, \dots, x_n)}{\partial (x_i)} \Big|_{x_i} \right)^2 \sigma_i^2$$

Assuming the Probability Distribution Function (PDF) of y to be also Gaussian ($N_y(y; \mu_y, \sigma_y)$), the probability of ($y > Y_0$) is given by:

$$P[y > Y_0] = \int_{Y_0}^{\infty} N_y(y; \mu_y, \sigma_y) dy = 1 - \int_{-\infty}^{Y_0} N_y(y) dy = 1 - \Phi_y(Y_0) \quad (3)$$

where, Φ_y is the Cumulative Distribution Function (CDF) of y . Let us assume $y = f(x_1, \dots, x_n)$ and $z = g(x_1, \dots, x_n)$ are two Gaussian random variables $N_y(y; \mu_y, \sigma_y)$ and $N_z(z; \mu_z, \sigma_z)$, respectively. The probability of ($y > Y_0$ & $z > Z_0$) is given by:

$$P[(y > Y_0) \& (z > Z_0)] = 1 - P[(y \leq Y_0) \& (z \leq Z_0)]$$

$$= 1 - \{P[y \leq Y_0] + P[z \leq Z_0] - P[(y \leq Y_0) \& (z \leq Z_0)]\} \quad (4)$$

$$= \{P[y > Y_0] + P[z > Z_0] - 1\} + \Phi_{y,z}(Y_0, Z_0)$$

where, $\Phi_{y,z}(y,z)$ is the joint CDF of y and z . In order to evaluate $\Phi_{y,z}(y,z)$ the correlation coefficient between y and z needs to be computed. The correlation coefficient (ρ) is given by:

$$\rho = \frac{E(yz) - E(y)E(z)}{\sigma_y \sigma_z} = \frac{E(yz) - \mu_y \mu_z}{\sigma_y \sigma_z}$$

$$E(yz) = f(\eta_1, \dots, \eta_n) g(\eta_1, \dots, \eta_n) + \frac{1}{2} \sum_{i=1}^n \frac{\partial^2 (fg)}{\partial (x_i)^2} \sigma_i^2 \quad (5)$$

$$= f_0 g_0 + \frac{1}{2} \sum_{i=1}^n \left(g_0 \frac{\partial^2 f}{\partial x_i^2} + 2 \frac{\partial f}{\partial x_i} \frac{\partial g}{\partial x_i} + f_0 \frac{\partial^2 g}{\partial x_i^2} \right) \sigma_i^2$$

The above results will be used in this paper to estimate the failure probabilities of different events.

3.2. Read Stability Failure (R_F)

While reading the cell shown in Fig. 1 ($V_L = '1'$ & $V_R = '0'$), due to the voltage divider action between AX_R and N_R , V_R increases to a positive value V_{READ} . If V_{READ} is higher than the trip point of the inverter P_L-N_L (V_{TRIPRD}), then the cell flips while reading the cell (Fig. 3(a)) [9]. This represents a *read failure* (R_F) event. Hence, the read-failure probability (P_{RF}) is given by:

$$P_{RF} = P[V_{READ} > V_{TRIPRD}] \quad (6)$$

V_{TRIPRD} and V_{READ} can be obtained by solving KCL at node L and R, respectively. The estimated value of V_{TRIPRD} and V_{READ} closely follows the MEDICI simulation result (Fig. 4). Assuming the PDF of V_{READ} ($=N_{RD}(V_{READ})$) and V_{TRIP} ($=N_{TRIP}(V_{TRIP})$) as Gaussian

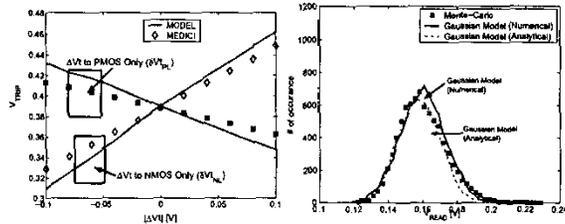

Fig. 4: (a) Variation of V_{TRIP} of P_L-N_L (b) Distributions of V_{READ}

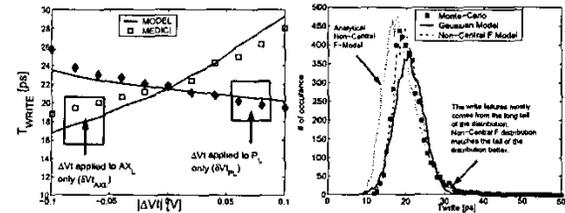

Fig. 5: (a) T_{WRITE} variation with δV_t (b) distribution of T_{WRITE}

distributions with the means the variances obtained using (2) (Fig. 4). P_{RF} is given by:

$$P_{RF} = P[Z_R \equiv (V_{READ} - V_{TRIPRD}) > 0] = 1 - \Phi_{ZR}(0) \quad (7)$$

where, $\eta_{ZR} = \eta_{V_{READ}} - \eta_{V_{TRIP}}$ and $\sigma_{ZR}^2 = \sigma_{V_{READ}}^2 + \sigma_{V_{TRIP}}^2$

3.3. Write Stability Failure (W_F)

While writing a '0' to a cell storing '1', the node V_L gets discharged through BL to a low value (V_{WR}) determined by the voltage division between the PMOS P_L and the access transistor AX_L [9]. If V_L can-not be reduced below the trip point of the inverter P_R-N_R (V_{TRIPWR}), within the time when word-line is high (T_{WL}), then a write failure occurs (Fig. 3b). The write-failure probability (P_{WF}) is given by:

$$P_{WF} = P[(T_{WRITE} > T_{WL})] \quad (8)$$

where, T_{WRITE} is the time required to pull down V_L from V_{DD} to V_{TRIPWR} . T_{WRITE} is obtained by solving:

$$T_{WRITE} = \begin{cases} \int_{V_{DD}}^{V_{TRIP}} \frac{C_L(V_L) dV_L}{I_{in(L)}(V_L) - I_{out(L)}(V_L)} & \text{if } (V_{WR} < V_{TRIPWR}) \\ \infty & \text{if } (V_{WR} \geq V_{TRIPWR}) \end{cases} \quad (9)$$

$I_{in(L)}$ = current into L $\approx I_{dsPL}$, $I_{out(L)}$ = current out of L $\approx I_{dsANL}$

where C_L is the net capacitance at the node L. V_{WR} can be obtained by solving KCL at node L & R [9]. V_{TRIPWR} can be obtained by solving for trip-point of the inverter P_R-N_R . T_{WRITE} obtained using (9) closely matches the MEDICI simulation result with V_t variation of different transistors (Fig. 5a). Using (2), we can estimate the mean (η_{TWR}) and the standard-deviation (σ_{TWR}) and approximate its pdf as a Gaussian one ($f_{WR}(T_{WR})$) (Fig. 5b). However, most of the write-failures originate from the 'tail' of the distribution function. Hence, to improve the accuracy of the model at the tail region, we can use a non-central F distribution [8]. Using the PDF (Gaussian/non-central F) of $T_{WRITE}(N_{WR}(T_{WR}))$, the P_{WF} can be estimated using (3).

3.4. Access Time Failure (A_F)

The cell access time (T_{ACCESS}) is defined as the time required to produce a pre-specified voltage difference ($\Delta_{MIN} \approx 0.1V_{DD}$) between two bit-lines (bit-differential). If due to V_t variation, the access time of the cell is longer than the maximum tolerable limit (T_{MAX}), an access time failure is said to have occurred. The probability of access time failure (P_{AF}) of a cell is given by:

$$P_{AF} = P(T_{ACCESS} > T_{MAX}) \quad (10)$$

While reading the cell storing $V_L = '1'$ and $V_R = '0'$ (Fig.1, Fig.3), bit-line BR will discharge through AX_R and N_R (by the current I_{BR}).

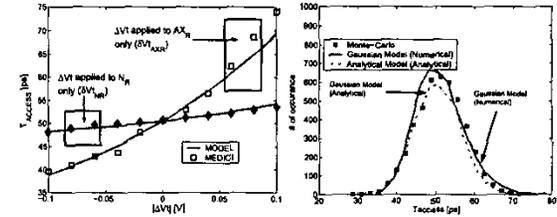

Fig. 6: (a) T_{ACCESS} variation with δV_t (b) distribution of T_{ACCESS}

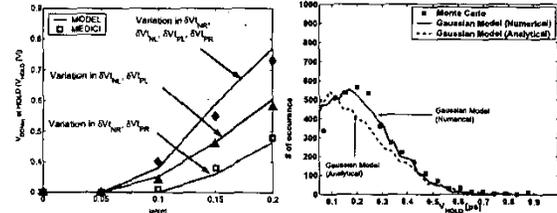

Fig. 7: (a) V_{DDmin} variation with δV_t (b) distribution of V_{DDmin}

Simultaneously, BL will discharge by the leakage of AX_L of all the cells (I_{BL}) connected to BL. Hence, the access time is given by:

$$T_{ACCESS} = \frac{C_{BR}C_{BL}\Delta_{MIN}}{C_{BL}I_{BR} - C_{BR}I_{BL}} = \frac{C_B\Delta_{MIN}}{I_{dsatAXR} - \sum_{i=1,\dots,N} I_{subAXL(i)}} \quad (11)$$

where, N is the #of cells attached to a bit-line (or column), C_{BR}/C_{BL} is the bit-line capacitance (assumed to be equal). The access time given by (11) closely follows the MEDICI simulation result (Fig. 6a). The PDF of T_{ACCESS} can be approximated as a Gaussian one with the mean (η_{TAC}) and the standard deviation (σ_{TAC}) obtained from (2) (Fig. 6b). Using the derived PDF ($N_{TACCESS}(t_{ACCESS})$), P_{AF} can be estimated using (3).

3.5. Hold Stability Failure (H_F)

In the stand-by mode, the V_{DD} of the cell is reduced to reduce the leakage power consumption. However, if the lowering of V_{DD} causes the data stored in the cell to be destroyed, then the cell is said to have failed in the hold-mode [10] (Fig. 3c). Hence, for a hold-failure event, the minimum supply voltage that can be applied to the cell in the hold-mode (V_{DDHmin}), without destroying the data, is higher than the designed stand-by mode supply voltage (V_{HOLD}). Thus, the probability of hold-stability failure (P_{HF}) is given by:

$$P_{HF} = P[V_{DDHmin} > V_{HOLD}] \quad (12)$$

Lowering the V_{DD} of the cell (say V_{DDH} represents the cell V_{DD} at the hold mode) reduces the voltage at the node storing '1' (V_L in Fig. 1). Due to leakage of N_L , V_L will be less than V_{DDH} for low V_{DDH} . The hold-failure occurs if $V_L < V_{TRIP}$ of P_R-N_R . Hence, V_{DDHmin} can be obtained by numerically solving:

$$V_L(V_{DDHmin}, \delta V_{PL}, \delta V_{NL}) = V_{TRIP}(V_{DDHmin}, \delta V_{PR}, \delta V_{NR}) \quad (13)$$

The estimated value of V_{DDHmin} using (13) closely follows the values obtained from MEDICI simulation (Fig. 7a). The distribution of V_{DDHmin} can be approximated as a Gaussian one with mean and variance obtained using (6) (Fig. 7b). Using the Gaussian pdf for V_{DDHmin} the P_{HF} can be estimated (using (3)).

3.6. Estimation of Overall Cell Failure Probability (P_F)

The overall failure probability is given by:

$$P_F = P[Fail] = P[A_F + R_F + W_F + H_F] = P_{AF} + P_{RF} + P_{WF} + P_{HF} - P[A_F R_F] - P[A_F W_F] - P[A_F H_F] - P[R_F W_F] - P[R_F H_F] - P[W_F H_F] + P[A_F R_F W_F] + P[A_F R_F H_F] + P[R_F W_F H_F] + P[W_F H_F A_F] - P[All] \quad (14)$$

An accurate estimate of the probability of joint events is possible by constructing the joint PDF representing two events using the procedure given in (4). We have also assumed that probabilities of simultaneous occurrence of more than two events are negligible (≈ 0). The estimated probabilities match the Monte-Carlo results very closely.

3.7. Estimation of Column and Memory Failure Probability

The failure probability of column (P_{COL}) (or row (P_{ROW})) is defined as the probability that any of the cells (out of N cells) in that column (or row) fails. Assuming a column redundancy, the probability of failure of a memory chip (P_{MEM}) designed with N_{COL} number of columns and N_{RC} number of redundant columns, is defined as the probability that more than N_{RC} (i.e. at least $N_{RC}+1$)

columns fail. Hence, P_{COL} and P_{MEM} can be given by:

$$P_{COL} = 1 - (1 - P_F)^N \quad \text{and} \quad P_{MEM} = \sum_{i=N_{RC}+1}^{N_{COL}} \binom{N_{COL}}{i} P_{COL}^i (1 - P_{COL})^{N_{COL}-i} \quad (15)$$

The exact estimation of the different failure probabilities requires numerical solutions of the KCL at different nodes. In order to reduce the computation complexity, analytical models of different failure probabilities were also obtained using simplified long-channel current equations. The distributions of V_{READ} , V_{TRIPD} , T_{ACCESS} , T_{WRITE} and V_{HOLD} using the analytical models are also shown in Figs. 4-7.

4. SENSITIVITY ANALYSIS OF FAILURE PROBABILITY

Fig. 8 shows that a weak access transistor (small W_{nax}) reduces P_{RF} (V_{READ} decreases); however, it increases P_{AF} and P_{WF} (Fig. 8) and has very small impact on P_{HF} . Reducing the strength of the PMOS pull-up transistors (by decreasing W_p) reduces P_{WF} (reducing I_{bSPL}), but increases P_{RF} (lowers V_{TRIPD}). P_{AF} does not depend strongly on PMOS strength (Fig. 8). P_{HF} improves with an increase in W_p as the node L is more strongly coupled to the supply voltage ($V_L \rightarrow V_{DDH}$). Increasing W_{npd} increases the strength of pull-down NMOSs (N_L & N_R). This reduces P_{RF} ($V_{READ} \downarrow$) and P_{AF} by increasing the strength of N_R (Fig. 8). Increase in width of N_R has little impact on P_{WF} . Although, it slightly increases the nominal value of T_{WRITE} , the reduction of σ_{VT} of N_R (see (1)) tends to reduce σ_{TWRITE} and hence P_{WF} remains almost constant. An increase in the V_{TRIP} of P_R-N_R initially reduces P_{HF} with the increase in W_{npd} . However, a higher width of N_L reduces V_L (from the applied V_{DDH}) due to an increase the leakage of N_L . Consequently, a very high W_{npd} increases the P_{HF} .

5. STATISTICAL OPTIMIZATION OF SRAM CELL

5.1. SRAM Yield Estimation Model

To estimate the yield, we have used Monte-Carlo simulations for inter-die distributions of L , W and V_t (assumed to be Gaussian). For each inter-die values of the parameters (say L_{INTER} , W_{INTER} and V_{tINTER}) we estimate P_F , P_{COL} and P_{MEM} considering the intra-die distribution of δV_t . Finally, the yield is defined as:

$$Yield = 1 - \left(\sum_{INTER} P_{MEM}(L_{INTER}, W_{INTER}, V_{tINTER}) \right) / N_{INTER} \quad (16)$$

where, N_{INTER} is the total number of inter-die Monte-Carlo simulations (i.e. total number of chips).

In order to maximize the yield P_{MEM} needs to be minimized. This requires optimum design of the cell configurations (i.e. length and width of transistors) and the number of redundant columns (N_{RC}). However, such an optimization of P_{MEM} has to consider the impact on the total leakage and the total area (A_{MEM}).

5.2. Estimation of Leakage in SRAM

The total leakage in a cell is principally consist of the subthreshold leakage, the gate leakage, and the junction BTBT leakage through different transistors in the cell (Fig. 1). The leakage current expressions presented in [5] are used to evaluate the different leakage components. The total memory leakage ($I_{LeakMem}$) is the summation of leakage of individual cells.

5.3. Area Estimation of SRAM

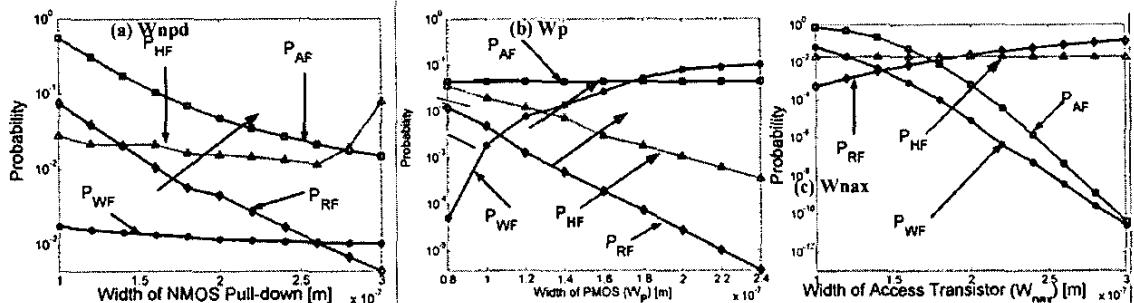

Fig. 8: Variation of Cell Failure Probabilities with Cell structure

The total memory area is given by:

$$A_{actual} = N_{ROW} N_{COL} A_{cell}; A_{redundant} = N_{ROW} N_{RC} A_{cell} \quad (17)$$

$$A_{MEM} = A_{actual} + A_{redundant} = N_{ROW} (N_{COL} + N_{RC}) A_{cell}$$

where, A_{actual} is the required memory area (given by the memory size) and $A_{redundant}$ is the area overhead of the redundant columns. A_{cell} is the cell area computed using the layout given in [11].

5.4. Optimization Procedure

The optimization problem can be stated as:

Minimize $P_{MEM} = f(X)$

where $X \equiv [L_{nax}, W_{nax}, L_{nps}, W_{nps}, L_{pup}, W_{pup}, N_{RC}]$

Subject to:

$$I_{LeakMem} \leq I_{LeakMax} \quad (18)$$

$$A_{MEM} \leq \text{Maximum Area } (A_{MAX})$$

$$E[T_{AC}] = \mu_{TACCESS} \leq \text{Maximum access time mean } (\mu_{TAC-MAX})$$

For all the parameters: $\{X_{MIN}\} \leq \{X\} \leq \{X_{MAX}\}$

This is essentially a non-linear optimization problem with non-linear constraints. The upper bound on the mean access time is given to ensure that robustness of the memory has not been achieved by significantly sacrificing performance. Fig. 9 shows the basic steps of the optimization process. The upper bound of N_{RC} is determined using (17) as shown below:

$$N_{RCmax} = \frac{A_{MEM} - N_{ROW} N_{COL} A_{cellmin}}{A_{cellmin} N_{ROW}} = \frac{A_{MEM}}{A_{cellmin} N_{ROW}} - N_{COL} \quad (19)$$

The minimization of P_F in step 5-7 requires the estimation of the joint probabilities given in (4) which are computationally expensive. However, it should be noted that:

$$P_F = P[A_F + R_F + W_F + H_F] \leq P_{AF} + P_{RF} + P_{WF} + P_{HF} = P_{FMOD} \quad (20)$$

Hence, instead of minimizing P_F we try to minimize P_{FMOD} . The above problem can be solved using *Lagrange Multiplier* based algorithm [12]. The Lagrangian formulation of the above problem is shown below:

$$\text{Minimize } f(X) = P_{FMOD}$$

where $X \equiv [L_{nax}, W_{nax}, L_{nps}, W_{nps}, L_{pup}, W_{pup}]$

$$\text{Subject to: } h_1(X) = (A_{cell} / A_{cellmax}(i)) - 1 \leq 0$$

$$h_2(X) = (I_{LeakMem} / I_{LeakMax}) - 1 \leq 0$$

$$h_3(X) = (\mu_{TAC} / \mu_{TAC-MAX}) - 1 \leq 0$$

In this work, we have considered the discrete variable space (to account for the minimum limit on the lithographic controllability of L and W) for $L_{nax}, W_{nax}, L_{nps}, W_{nps}, L_{pup}$ and W_{pup} . To solve the discrete space Lagrangian problem, we have used the Discrete Lagrangian Method (DLM) described in [12,13].

6. OPTIMIZATION RESULTS

The optimization methodology described earlier is used to optimize the cell structure (from [14]) and the use of redundancy to minimize the memory failure probability (Table-I). To improve the beta ratio between the pull-up PMOS and access transistor, the original cell was designed with a longer PMOS. However, a weaker PMOS tends to increase the read failure. Hence, the optimization reduces the length of the PMOS and uses the extra area in the pull-down NMOS, thereby reducing the access failure. The proposed optimization algorithm allows to trade-off between the redundancy area and the active cell area. Reducing the number of redundant column allows more area for each of the actual cells. This reduces the failure probability of the cells, thereby reducing P_{MEM} . On the other hand, from (15) it can be observed that reducing N_{RC} will tend to increase P_{MEM} . Fig. 10 shows the variation of P_{MEM} with the variation of N_{RC} considering constant A_{MEM} . It can be observed that increasing the redundancy beyond a certain point increases the memory failure probability. It should be further noted that with the application of a higher value of the σ_{Vth} , the optimized value of the redundancy (that minimizes failure probability) reduces. This

1. Determine the bounds on N_{RC} and initialize:
 $i=0, N_{RC}(0)=N_{RCmin}, P_{MEMmin}=1$
2. **repeat**
3. Determine maximum allowable cell area:
4. $A_{cellmax}(i) \leq A_{MAX} / [N_{ROW} (N_{RC}(i) + N_{COL})]$
5. Solve the following optimization problem
6. Minimize $P_F(L_{nax}, W_{nax}, L_{nps}, W_{nps}, L_{pup}, W_{pup})$
7. Subject to: $A_{cell} \leq A_{cellmax}(i); P_{LeakPower} \leq P_{LeakMin}; \mu_{TAC} \leq \mu_{TAC-MAX}$.
8. Calculate $P_{COL}(i)$ and $P_{MEM}(i)$ using the optimum P_F and $N_{RC}(i)$.
9. **If** $P_{MEM}(i) < P_{MEMmin}$ **Then** $P_{MEMmin} := P_{MEM}(i)$
10. **until** $N_{RC}(i) = N_{RCmax}$

Fig. 9: Optimization procedure

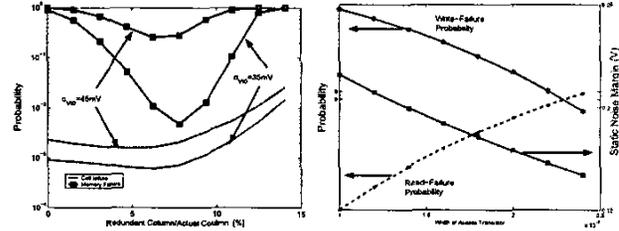

Fig. 10: impact N_{RC} on memory yield. Fig. 11: Impact of SNM on failure probability of SRAM cell

Table I: optimization results							
	β_{nax}/β_p	β_{nps}/β_{nax}	P_F	P_{MEM}	I_{Leak}	T_{AC}	Yield
Cell [11]	1.5	1.36	2.6e-3	0.034	851 μ A	55ps	47%
Opt. Cell	1.2	1.48	3.4e-5	0.001	950 μ A	46ps	95%

indicates that with larger amount of variations, design of robust cell is more effective in reducing the failure probability (improving yield) as compared to increasing number of redundant columns. Hence, it can be concluded that a statistical analysis of effectiveness of the redundancy is necessary to improve the memory failure probability.

The static noise margin (SNM) of a cell is often used as a measure of the robustness of an SRAM cell against flipping [1]. However, an increase in SNM makes the cell difficult to write by increasing its data holding capability, which increases write failures (Fig. 11). Consequently, an increase in the SNM does not necessarily reduce the overall failure probability. Using the proposed models, it is observed that SNM does not have a strong relationship with the parametric failure of the memory.

7. CONCLUSION

In this work, we have proposed a semi-analytical method to estimate the failure probability of an SRAM cell and memory due to parameter variations. The derived models have been used to predict the yield of memory at an early stage of a design. The proposed models are used for statistical optimization of memory design, which is necessary for maximizing yield in nano-meter regimes.
